1 Introduction

1.1 Question

To what extent does the given spring behave as an ideal spring?

1.2 Hypothesis

As seen previously in physics class, the force exerted by an ideal spring is modeled by Hooke's Law, $F = -kx$, where k is the spring-force constant. This k is considered, in the ideal spring, to be a fixed scalar value and a property intrinsic to the spring. While this model is precise for most practical purposes, a real, non-ideal spring will not conform to this model.

In order to recognize how regularly the spring conforms to the model of the ideal spring, we observe and compare how the spring oscillates over a range of forces and displacements. By suspending weights of varying mass from the spring and displacing those weights, we create an oscillation that can be measured and allow the spring force constant to be calculated. In an ideal spring, the spring-force constant would be constant. Observing a variation in this value would indicate conditions where the spring deviates from the ideal modeled by Hooke's Law.

1.3 Method

1. Setup the rig displayed in the diagram below.
2. Place tape on the bottom of the mass to hold the note card.
3. Pull the mass down directly above the motion detector from the springs equilibrium 2 inches down and release.
4. Record data using the Labquest.
5. Find the period of each mass.
6. Test various weights to see how that affects the k value.
7. Repeat steps as needed.

Equipment	Purpose
Ring stand	Suspend the spring and mass.
Spring	Spring whose characteristics are observed.
Hanging masses	Masses range from 10 g to 1 kg.
Meter stick	To estimate displacement from equilibrium.
Motion detector	Record displacement of spring at regular intervals of time.
Labquest	Control the motion detector and receive data.
Computer	Control the Labquest controller and receive data.
1 Note Card	Act as reflector for motion detector.
Tape	Fix the note card to the suspended mass.

1.4 Predictions

We expect that the frequency of the spring oscillation should be consistent and regular until we add very large masses. With larger masses, at the extremes of force and displacement, the spring will deform and no longer behave as an ideal spring.

2 Data Collection

2.1 Observations

During the lab, we noticed the spring was very resilient in not deviating from Hooke's law from the amount of mass we added where the spring would no longer be a ideal spring. We also noticed that we couldn't get the spring to deviate during experimentation due to lack of space and height for the ring stand, refer to Figure 1.2. This was also our first time using the lab quest and we were having a little trouble getting the lab quest to take more samples during the set time.

3 Analysis

3.1 Method

Per Hooke's Law, the position can be represented as a function of time as a solution to the differential equation,

$$m \frac{d^2 x}{dt^2} = -kx \quad (1)$$

where x is the position of the spring, t is time, m is the mass on the spring, and k is the spring force constant. It can be seen that $x = A \cos(\omega t)$ is a solution to this equation, where $\omega^2 = \frac{k}{m}$. This implies that the frequency of the spring oscillations is a function of the mass and spring force constant, and can easily be obtained by modeling the spring's motion as a sinusoidal function.

It would be difficult to calculate frequency of the spring oscillations directly, as the sampling rate of the motion detector was relatively low, but could be interpolated using the model. The data was fit to a cosine function by least-squares fitting with a Python script.

The data for each trial, as exported by the Labview software, was fit to a cosine function using the SciPy.optimize package's leastsq method. This implements the Levenberg-Marquardt algorithm. The initial parameters were estimated by reviewing the data. Iterating over the data points, the local peaks were identified (as local maxima above the mean) and frequency was estimated to be the mean of the distances between them. Amplitude was estimated to be half the distance between minimum and maximum position values. Phase offset was guessed from the time of the first local maximum in position, and

the position off-set was taken from the mean of all position values. For some trials, the bottom of the mass was within the minimum range of the motion detector and yielded a position value near that boundary of range. It was thus necessary to filter out position values in that region.

The curve-fitting algorithm calculated the modeling function's frequency term, ω . As stated above, Hooke's Law would imply that the spring force constant k can be expressed $k = m\omega^2$. Thus, the spring force constant could quickly be calculated from the results of the curve fitting algorithm.

3.3 Limitations and Improvements

With the trials performed with small masses, the frequency of the spring's oscillations were near the sampling frequency of the motion detector. With fewer data points at each cycle of the oscillation, it is more difficult to accurately fit the motion to a curve. Similarly, with the low frequency of oscillations in the trials with large masses, it was only possible to observe one complete cycle of the spring's motion. Observing the motion for a longer period would improve the quality of the fit. If it were possible to use a motion detector with a higher sampling rate, the fit of the earlier trials with lesser masses would be improved.

With a few of the trials, particularly those with the greatest masses, there

was no room to suspend the mass above the minimum range of the motion detector, causing the observed wave form to be clipped as it approached the motion detector. This can be seen in Figure 3.14. This created regions in the data that needed to be filtered and led to a poorer fit to the curve. Similarly, this lack of vertical laboratory space put an upper limit on the masses we were able to use in the experiment.

The quality of the results would be much improved if the data reduction algorithm were extended to use the least-square residuals to estimate uncertainty. This is certainly technically possible but we beyond the expertise of the group's programmer.

Figure 3.16: Mass (kg) - Spring Constant k

4 Interpretation

As can be observed in Figure 3.16, the calculated spring force constant is relatively consistent for masses between 200 g and 1 kg. At smaller masses, the calculated spring force constant deviates considerably from the other values and appears to increase at a logarithmic rate. There is also variance with masses above 1 kg, but as it was difficult to accurately record the displacement with those masses, this may reflect the limitations of the experimental setup.

The spring proved to be very stiff and resilient. It is possible that with small masses, the suspended mass was bouncing or swinging at the point where it was fastened to the spring. This would skew calculations considerably, as it would essentially become a two-oscillator (a pendulum as well as a spring) system. It could also be that the physical characteristics of the spring, the flexing and stiffness of the metal, varies at very small displacements. In any case, the ideal spring model was not consistent with very small masses.

The spring was expected to break down with the greatest masses, but it was much more resilient than expected and was relatively consistent at the largest displacements we were able to observe. The spring behaves very near the ideal model for the greatest displacements that were practically achieved in the laboratory conditions.

There did appear to be some observable inconsistency in the spring force constant with masses in the range of 200 g and 1 kg. With additional data points it may be possible to perform a statistical regression and develop a more precise model of the spring force constant as it varies with displacement.
